1 Problem 1

(50 points) Now you' ve learned the RC4 scheme (one of the stream cipher of symmetric key encryption). Denote $KeyGen(\lambda)$ as the key generation algorithm: pick a uniform $k \in \{0,1\}^{128}$, and output k. Denote m as a message of l bytes and c as the ciphertext. Please use your own words (or pesudocode) to describe the encoding algorithm $Enc(k,m)$ and decoding algorithm $Dec(k,c)$.

Hints: 1) The Enc determines the format of ciphertext output. 2) A stream cipher need synchronized information between encryption and decryption side (why?). Consider a real example: after A and B shared secret key k, A is going to send message m1 to B in the first day and send message m2 to B in the second day. In the meanwhile, A and B' s computers running Enc/Dec may shut down or restart due to failure. Take a look at whether your algorithms can support this example safely and conveniently.

(a) $Enc(k,m)$.

Answer: In order to ensure the correctness of **RC4 Algorithm** in different sistuations, we need to implement the synchronization of this stream ciphers. Thus, we design our strategy with reference to **self-synchronized stream cipher***:

1. Let t denotes the number of encryption registers, which stores the ciphertext bytes that transformed before.
2. t bytes in these encryption registers are set to be $1, 2, ..., t$ and initialized with secret key key.
3. Once we've transfered a byte, we store this byte into one of these encryption registers, and remove it after t rounds. We replace the earlist byte that entered encryption registers with this byte.
4. We use these t bytes in encryption registers as our internal states S, which means that these t bytes will influence the generation of our key stream.
5. We generate our key stream by using maximum and minimum elements in S, which don't pay attention to the order of elements in S (in order to implement self-synchronized). That is, **compared with the change on number order of basic RC4 algorithm, we change the element itself.**

*Stream Ciphers: https://blog.csdn.net/qq_43721475/article/details/104661762

Based on the strategy above, we give the pesudocode of our Encryption algorithm (let $t = 256$):

Algorithm 1: Encryption Algorithm $Enc(k, m)$ of RC4

Input: Uniform secret key $k \in \{0,1\}^{128}$; Message m of l bytes
Output: Ciphertext c of l bytes.

```
byte key[16] ;                                   // secret key
byte K[256] ;                                    // keying material
byte S[256] ;           // internal states (encryption registers)

for i = 0 to 255 do
    S[i] = i;
    K[i] = key[i mod 16];
j = 0;
for i = 0 to 255 do
    j = (j + S[i] + K[i]) mod 256;
    S[i] = (S[i] + S[j] + K[j]) mod 256 ;   // initialize S with key
     materials

for idx = 0 to l do
    max = max{S[i] | i = 0, 1, ..., 255} ;   // maximum element in S
    min = min{S[i] | i = 0, 1, ..., 255} ;   // minimum element in S
    t = (S[max] + S[min]) mod 256 ;          // Begin encryption
    c[idx] = m[idx] ⊕ S[t];
    Replace earlist byte that entered S with c[idx]

return c;
```

Proof.

1. **Secrecy.** Obviously, the generated key stream both rely on the secret key and the previous ciphertext bytes, and has enough randomness, which can ensure the secrecy of our algorithm.

2. **Self-synchronized.** If one of the ciphertext bytes comes to failure during transformation, obviously after t rounds of transformation, this failure will be automatically corrected, which means that this failure will only influence t ciphertext bytes during transformation.

(b) $Dec(k, c)$.

Answer: The pesudocode of our Decryption algorithm is:

Algorithm 2: Decryption Algorithm $Dec(k, c)$ of RC4

Input: Uniform secret key $k \in \{0,1\}^{128}$; Ciphertext c of l bytes
Output: Message m of l bytes.

```
byte key[16] ;                                  // secret key
byte K[256] ;                                   // keying material
byte S[256] ;         // internal states (encryption registers)

for i = 0 to 255 do
    S[i] = i;
    K[i] = key[i mod 16];
j = 0;
for i = 0 to 255 do
    j = (j + S[i] + K[i]) mod 256;
    S[i] = (S[i] + S[j] + K[j]) mod 256 ;   // initialize S with key
     materials

for idx = 0 to l do
    max = max{S[i] | i = 0, 1, ..., 255} ;   // maximum element in S
    min = min{S[i] | i = 0, 1, ..., 255} ;   // minimum element in S
    t = (S[max] + S[min]) mod 256 ;             // Begin encryption
    m[idx] = c[idx] ⊕ S[t];
    Replace earlist byte that entered S with c[idx]

return m;
```

2 Problem 2

(50 points) Suppose the key for a cipher is an l-bit binary string.

(a) What is the key space size of this cipher?.

Answer: The key space size of cipher is 2^l.

(b) To find a key by exhaustive key search, how many keys does an attacker need to test on average?.

Answer: It's reasonable to assume that the probability distribution of key is uniform distribution. That is, the probability of each value of key is $\frac{1}{2^l}$. Therefore, the average times an attacker need to test by exhaustive key search is:

$$\tfrac{1}{2^l} \times \textstyle\sum_{i=1}^{2^l} i = \tfrac{1}{2^l} \times (1 + 2^l) \times 2^{l-1} = 2^{l-1} + \tfrac{1}{2}$$
